Monopsony in Motion: Imperfect Competition in Labour Markets

Alan Manning

Chapter 1
Introduction

Introduction

What happens if an employer cuts the wage they pay their workers by one cent? Much of labour economics is built on the assumption that all existing workers immediately leave the firm as that is the implication of the assumption of perfect competition in the labour market. In such a situation an employer faces a market wage for each type of labour determined by forces beyond their control at which any number of these workers can be hired but any attempt to pay a lower wage will result in the complete inability to hire any of them at all. The labour supply curve facing the firm is infinitely elastic.

In contrast this book is based on two assumptions about the labour market. They can be stated very simply:

S there are important frictions in the labour market

S employers set wages

The implications of these assumptions can also be stated simply. The existence of frictions means that there are generally rents to jobs i.e if an employer and worker are forcibly separated one or, more commonly, both of the parties would be made worse-off. This gives employers some market power over their workers as a small wage cut will no longer induce them to leave the firm. The assumption that employers set wages then tells us that employers exercise this market power. But, with these two assumptions, it is monopsony not perfect competition that is the best simple model to describe the decision problem facing an individual employer. Not monopsony in the sense of there being a single buyer of labour, but monopsony in the sense of the supply of labour to an individual firm not being infinitely elastic. The actions of other
employers (notably their choice of wages) in the market will affect the supply of labour to an individual firm so, if one wants to model the market as a whole, models of oligopsony or monopsonistic competition are what is needed\(^1\). The usefulness of the monopsonistic approach rests on the two assumptions so they need some justification.

That important frictions exist in the labour market seems undeniable: people go to the pub to celebrate when they get a job rather than greeting the news with the shrug of the shoulders that we might expect if labour markets were frictionless. And people go to the pub to drown their sorrows when they lose their job rather than picking up another one straight away. The importance of frictions has been recognised since at least the work of Stigler (1961, 1962).

What are the sources of these frictions in labour markets? In the A\textit{Economics of Imperfect Competition}®, Joan Robinson argued that:

“there may be a certain number of workers in the immediate neighbourhood and to attract those from further afield it may be necessary to pay a wage equal to what they can earn near home plus their fares to and fro; or there may be workers attached to the firm by preference or custom and to attract others it may be necessary to pay a higher wage. Or ignorance may prevent workers from moving from one to another in response to differences in the wages offered by the different firms® (Robinson, 1933, p296)

It is ignorance, heterogeneous preferences and mobility costs that are the most plausible

---

\(^1\) The Oxford English Dictionary credits the word monopsony to Joan Robinson (1933) though she credits it to B.L.Hallward a classical scholar at Cambridge who though born in 1901 is still alive at the time of writing. The suffix is derived from OPSONEN which means \(\Delta\)to make your purchases often of dried fish\(\Delta\) and which is found in Aristophanes, the Wasps (twice), Plutarch and the New Testament. The natural ONEOMAI (\(\Delta\)I buy\(\Delta\)) was rejected as it does not sound good with the MONO prefix (personal communication to David Card). The invention of the word oligopsony is credited to Walker (1943) who introduced it with the curious phrase "it is surely only a matter of time before market situation number 23 is christened oligopsony", the time referred to being the time necessary for him to finish writing the sentence.
sources of frictions in the labour market. The consequence of these frictions is that an employer that cuts wages does not immediately lose all their workers. They may find that their workers quit at a faster rate than before or that recruitment is more difficult, but the extreme predictions of the competitive model do not hold. The labour supply curve facing the firm is, as a result, not infinitely elastic. The existence of frictions gives employers potential market power over their workers. The assumption that firms set wages means that they actually exercise this power. Let us now consider this assumption in more detail.

Given the existence of rents caused by frictions one needs to specify how they are divided between employer and worker. The existence of the rents makes the relationship between workers and employer one of bilateral monopoly (in part) so that we need a theory of how the rents are divided. The development of such a theory is an old problem in economics in general and labour economics in particular, going back to the discussion of Edgeworth (1932) where he argued that the terms of exchange in bilateral monopoly were indeterminate. This indeterminacy has never been resolved².

Given this problem at the heart of economics that this book is going to make no attempt to solve, there seems little alternative but to grasp the nettle and make some assumption about the way in which the rents are divided. One should choose an assumption that is a reasonable approximation to reality. This is made difficult by the fact that there is no universally right assumption for how rents are shared in the labour market: there are different mechanisms in different labour markets, perhaps even co-existing in the same labour market. In spite of this we

²For example, in recent years, there has been considerable interest in models of bargaining in bilateral monopoly following on the work of Rubinstein (1982) who, for a particular specification of the negotiation process between the two parties, showed that there was a unique equilibrium i.e. a determinate outcome. But this literature does not really solve the indeterminacy problem, it just pushes it back one more stage for the rules of the negotiation process generally determine the division of the rents and these rules are essentially arbitrary. So the indeterminacy problem re-emerges in the indeterminacy of the rules of the game.
will focus on one mechanism for most of this book.

In this book it is assumed that firms set wages\(^3\). This is a more appropriate assumption in some labour markets than others. For example, it would not seem to be appropriate when workers are organized into a union (we will have something to say about the consequences of this in chapter 12), or for senior management who often seem to have considerable ability to set their own wages, or for the self-employed or (most importantly of course) for academic labour economists. But, for the average worker in a non-union setting this does seem to be the appropriate assumption. Open the pages of a newspaper and one sees firms advertising jobs at given wages. One also sees advertisements saying "salary negotiable" though typically only for higher level jobs and the extent to which they are actually negotiable is often rather limited. But it is very rare to see advertisements placed by workers setting-down the wage at which they are prepared to work.

This view that the relationship between the employer and worker is one-sided has a long tradition. In the *Wealth of Nations* Adam Smith (1976, p84) wrote that \(\text{Ain the long-run the workman may be as necessary to his master as his master is to him; but the necessity is not so immediate}@. And Alfred Marshall in his *Principles of Economics* (1920, p471) wrote that \(\text{A} \text{labour is often sold under special disadvantages arising from the closely connected group of facts that labour power is } >\text{perishable}=, \text{that the sellers of it are commonly poor and have no reserve fund, and that they cannot easily withhold it from the market}@. To these arguments that a worker is typically more desperate for work then an employer is desperate for that particular worker, Sidney and Beatrice Webb (1897, p657-8) added the argument that \(\text{A the manual worker is, from his position and training, far less skilled than the employer } . \text{ in the art of bargaining}\)

\(^3\) Section 1.3 below compares this assumption about wage-setting with a prominent alternative, the ex post bargaining used in much of the matching literature (see Mortensen and Pissarides (1999) for a recent survey).
itself. This art forms a large part of the daily life of the entrepreneur, whilst the foreman is specially selected for his skill in engaging and superintending workmen. The manual worker, on the contrary, has the smallest experience of, and practically no training in, what is essentially one of the arts of the capitalist employer. He never engages in any but one sort of bargaining, and that only on occasions which may be infrequent, and which in any case make up only a tiny fraction of his life.

The view that the relationship between employer and worker is not one of equals was the origin of pro-labour legislation in many if not all countries. Section 1 of the US National Labor Relations Act of 1935 says “the inequality of bargaining power between employees who do not possess freedom of association or actual liberty of contract, and employers who are organized in the corporate and other forms of ownership association substantially burdens and affects the flow of commerce.” Our assumption that employers set wages is in this tradition.

The claim that labour markets are, in the absence of outside intervention, pervasively monopsonistic probably comes as something of a surprise to readers of labour economics textbooks. Table 1.1 documents the number of pages devoted to a discussion of monopsony and the total length in a selection of popular textbooks. As can be seen, monopsony does not figure prominently and, where it is mentioned, the discussion is generally not favourable: the final column of Table 1.1 contains a selection of quotes some of which capture the idea that frictions give employers some market power but most of which don’t⁴. There is a noticeable trend in the most recent textbooks towards less hostile views⁵ and a recognition that it is the existence of labour market frictions that is the main argument for the relevance of monopsony. But, while the

⁴ My personal favourite is taken from the first edition of Fleisher and Kniesner (1980, pp203-4) “we feel confident that monopsony is not a widespread phenomenon today. The primary reason is that fame and financial awards await the researcher who can demonstrate empirically that a significant number of workers are victims of monopoly power of employers. As yet, no one has claimed these prizes.”
⁵ A trend that can be confirmed by a fixed effect estimator, comparing the discussion of monopsony in different editions of the most popular textbooks.
overall perspective on the plausibility of monopsony may be changing, the range of labour market issues that contain some discussion of the implications of monopsony remains very limited. The first two volumes of the Handbook of Labour Economics (Ashenfelter and Layard, 1986) contain only two references to monopsony out of a total of 1268 pages, one in the chapter on dynamic labour demand by Nickell and the other in the chapter on discrimination by Cain. The three subsequent volumes published in 1999 (Ashenfelter and Card, 1999) contain three references in 2362 pages, in the chapters on labour market institutions, minimum wages and matching.

These statistics might be thought to be a little unfair for two reasons. First, many of these textbooks interpret monopsony literally as being a situation of a single employer of labour rather than the interpretation of an upward-sloping supply curve of labour that is used here. But, mentions of oligopsony are even fewer than mentions of monopsony and the general impression given by most textbooks is that employers have negligible market power over their workers or that this is, at best, a trivial side-issue.

This situation contrasts strongly with the situation in another part of economics, Industrial Organisation, where the standard assumption is that all firms have some product market power, although some are thought to have more market power than others. As a result, the bulk of the Handbook of Industrial Organization is about imperfect competition in product markets and virtually every chapter has some reference to monopoly or oligopoly. This contrast between Labour Economics and Industrial Organization is odd given that one might think frictions are more important in the labour market as it is more costly to change one's job than one's supermarket. The premise of this book is that labour economics should adopt a similar

---

6 For example, individuals in the British Household Panel Survey commonly reported employment-related events as major life events but none report that one of the most important things that happened to them in the past year is that they stopped shopping at Sainsburys and started going to Tescos.
attitude to that in Industrial Organization and start analysis from the position that all employers have some labour market power.

This book discusses most if not all of the issues in labour economics from the starting-point that the labour market is monopsonistic. Given the evidence cited above on the paucity of references to monopsony in textbooks one might expect a radical reworking of labour economics. Such an expectation will, more often than not, lead to disappointment. Often, we will be able to draw heavily on existing work and simply look at issues from a different angle: ‘re-packaging labour economics’ might be a more accurate sub-title than ‘re-thinking labour economics’.

Many explanations of labour market phenomena implicitly assume that the labour market is monopsonistic without articulating that fact. Perhaps the best example of this is search theory, an approach used to analyse a wide range of issues. The early developments, following Stigler (1962) were one-sided treating the distribution of wage offers in the market as exogenous. Stigler (1962) provides a careful and interesting discussion of why the law of one wage is likely to fail in the labour market but does not consider the process of wage-setting from the perspective of employers. But, when the process of wage determination was considered the early models often seemed to collapse and were incapable of explaining the existence of a non-degenerate wage distribution, a point made forcefully by Diamond (1971) and Rothschild (1973).

All of the models then developed to explain the existence of equilibrium wage dispersion (e.g Butters (1977)) essentially assume that firms have some market power. It would be an exaggeration to say that all coherent models of frictions imply firms have some market power but it is close to the truth\(^7\).

\(^7\)It is instructive to consider the models of frictions that do not give employers some market power. In the model of Lucas and Prescott (1974), workers must make a decision about the island on which to work before the realisation of island-specific demand shocks. There are frictions as there is no ex post mobility between islands after the realisation of the shocks. But, even though there are frictions, workers get paid their marginal product as Lucas and Prescott use a wildebeest model of the labour market in which each island has huge herds of employers who bid the wage up to the marginal product. Somewhat similar are the models of Moen (1997), Acemoglu and Shimer
1.1 The Advantages of a Monopsonistic Perspective

The main advantage of the monopsonistic approach is that the way one thinks about labour markets is more natural and less forced. Currently, labour economics consists of the competitive model with bitsbolted onto it when necessary to explain away anomalies. The result is often not a pretty sight. A good example is the analysis of the returns to specific human capital. If one is a strict believer in perfectly competitive markets, one should believe that workers get no return from firm-specific human capital: as Becker (1993, pp41-2) puts it “one might plausibly argue that the wage paid by firms would be independent of training”. But, Becker goes on to argue that employers need to give workers some share to deter quits, an idea formalized by Hashimoto (1981) which is the standard reference for this conclusion. But, (and this is discussed in more detail in chapter 5), Hashimoto simply assumes that the supply of labour to the firm is not perfectly elastic i.e. he assumes the labour market is monopsonistic, a rather helpless fudge that has sown only confusion ever since.

Assuming labour markets are monopsonistic also brings the thinking of labour economists in line with the way in which agents perceive the workings of labour markets. Workers do not perceive labour markets as frictionless and changing, getting or losing a job are routinely reported as major life-events: for example, in the UK British Household Panel Survey (BHPS), job-related events are the most common category of self-reported important life events after births, deaths and weddings. And, employers perceive they have discretion over the wages paid. Human resource management textbooks routinely state that the choice of the wage affects

---

(2000) and Burdett, Shi and Wright (2001) where each ‘island’ has only one firm, workers have an ex ante free choice of islands and the uncertainty about the demand shock is replaced by a matching friction in which it is hard to get employment once one is on an island. However, it is assumed that each firm commits in advance the wage it is going to pay so that the relevant labour supply curve is the perfectly elastic ex ante supply curve rather than the completely inelastic ex post one.
the ability of the employer to recruit and retain workers (see, for example, Jackson and Schuler, 2000, chapter 10) and the choice of a wage is a very real one.

It is simple to give examples of how a monopsonistic perspective makes life more comfortable for labour economists. The existence of wage dispersion for identical workers can readily be explained as the natural outcome of a labour market in which the competitive forces are not so strong as to make it impossible for low-wage employers to remain in existence: no recourse is needed to ‘unobserved ability’ to deny the existence of the phenomenon. When we find that workers paid, other things equal, higher wages are less likely to be looking for another job or that they are less likely to leave their employers this can be readily explained by the fact that these workers have been lucky enough to find themselves in one of the good jobs in their segment of the labour market. It does not have to be explained away in terms of higher-wage workers having more specific human capital (see, for example, Neal, 1998).

Similarly, the robust empirical correlation between employer characteristics and wages does not have to be explained away in terms of unobserved worker quality: it is exactly what one would expect to find in a monopsonistic labour market. When one observes that employers pay for general training for their workers, one does not have to claim that such training is really specific or that workers are paying for it indirectly. It is what one would expect in a monopsonistic labour market in which part of the returns to general training will accrue to employers.

When we find that equal pay legislation that substantially raises the pay of women, and

---

8Issues of labour quality muddy this as, in a competitive labour market, the choice of a wage is really the choice of quality of labour to employ on a job. But, if the competitive model of a labour market was correct, a firm that pays all its workers on a particular job the same wage (such firms are easy to find - see chapter 5) should have no variation in quality among these workers. There would be no such thing as a 'most-valued' worker. However, employers are aware that there is heterogeneity in the quality of workers who are paid the same wage. So, it is probably best to think of the wage paid as affecting both the quantity and quality of workers – see Manning (1994) for the working-out of a model with this feature.
does not appear to harm their employment, this is readily explained by a monopsonistic perspective but a serious problem if one believes the labour market is perfectly competitive. Similarly, finding that the minimum wage does not harm employment prospects in some situations is no particular mystery if one believes in monopsony.

Other examples could be added and are discussed at various points in this book. But, many labour economists instinctively feel very uncomfortable with the idea that labour markets may be pervasively monopsonistic and the next section tries to allay some of these fears.

1.2 Objections to Monopsony and Oligopsony

Many labour economists find the claim that labour markets are pervasively monopsonistic inherently implausible. It is doubtful that anyone would claim literally that the labour supply curve facing a firm is, in the short-run, infinitely elastic as the perfectly competitive model assumes. Almost certainly, most labour economists think of the elasticity as "high" and that the competitive model provides a tolerable approximation to reality. But, once one concedes that the competitive model is not literally true it becomes an empirical matter just how good an approximation it is. The claim of this book is that, for many questions, the competitive model is not a tolerable approximation and that our understanding of labour markets would be much improved by thinking in terms of a model where the labour supply curve facing the firm is not infinitely elastic.

The belief that the elasticity of the labour supply curve facing a firm is infinitely elastic is not based on any great weight of accumulated empirical evidence. The number of papers written about the elasticity of the labour supply curve at firm-level can almost be counted on the fingers on one hand (see the discussion in chapter 4). Rather, it is introspection (or revelation) which is the source of the faith of many labour economists in the irrelevance of monopsony.
There are a number of sources of this faith. First, there is the belief that large employers are necessary for employers to have some market power and that the vast majority of employers are small in relation to their labour market (Bunting, 1962, is the classic reference for US evidence on this). But the approach developed in this book does not require employers to be large in relation to their labour market. It only requires that a wage cut of a cent does not cause all workers to leave employment immediately.

Secondly, some labour economists argue that labour turnover rates are so high that workers cannot be thought of as tied to firms. But, the level of labour turnover is irrelevant: the issue is the sensitivity of labour turnover rates to the wage. Existing studies of this find that separations are related to the wage but that the elasticity is not enormous (again, this literature is discussed further in chapter 4).

Some other labour economists think that the supply of labour to a firm is irrelevant because they believe that the normal state of affairs is that employers are turning away workers who want a job at prevailing wages. Involuntary unemployment might be taken as one piece of evidence in this respect, low vacancy rates as another. But, we will argue (in chapter 9) that the existence of monopsony and involuntary unemployment are essentially orthogonal issues. Employers have market power over their workers whenever the elasticity of the supply of workers who the employer might consider employing is less than infinite, while involuntary unemployment exists when the supply of the workers that the employer would want is less than the supply who would like to work at the going wage.

And, we will argue (in chapter 10) that low vacancy rates and durations are perfectly consistent with the existence of labour supply being a constraint on employers. As job creation is costly, firms will not create jobs they do not expect to be able to fill. Hence, one should think of vacancies as "accidents" and a low vacancy rate is perfectly consistent with employers having
some monopsony power.

Thus, the faith that so many labour economists have in the irrelevance of monopsony or oligopsony is not based on hard evidence and the throw-away arguments sometimes heard are not as compelling as generations of labour economists have been led to believe. The idea deserves to be given more serious consideration and that is the aim of this book.

In much of the previous discussion, the idea of a monopsonistic labour market has been compared to the ideal of a frictionless labour market. But, there are other labour market models which acknowledge the existence of frictions yet would not commonly be thought of as monopsony models. Perhaps the most prominent example of these models is the Diamond-Pissarides matching model (see Diamond, 1982; Pissarides, 1985). How these models relate to the monopsony model is the subject of the next section.

1.3 Monopsony or Matching or Both?

Another tradition in labour economics, commonly called matching models (see Mortensen and Pissarides, 1999, for a recent survey), also start from the premise that there are important frictions in labour markets. But, these models differ from monopsony models in the assumptions made about wage determination. There are two main such differences (see Mortensen, 1998, for an explicit formal comparison of the two approaches).

First, there is a difference in the assumption about the bargaining power of workers. In monopsony models, it is assumed that employers set wages unilaterally whereas the matching models typically assume some process of wage bargaining between employer and worker (although one could set up these models so that employers have all the bargaining power)\(^9\).

\(^9\)Adam Smith (1976, p84) had something to say the practice of economists to see bargaining power of workers everywhere: Awe rarely hear, it has been said, of the combinations of masters; though frequently of those of workmen. But whoever imagines, upon this account, that masters rarely combine, is as ignorant of the world as of
Secondly, there is a difference in the assumption made about the timing of wage determination. In the formal models of monopsony introduced in the next chapter, wages are modeled as being determined prior to an employer and a worker meeting each other: this is often called ex ante wage-posting. In contrast, matching models typically assume that wages are determined after employer and worker have met (this is often called ex post wage bargaining).

If one judges theories by the realism of their assumptions then I believe that the wage-posting monopsony model is to be preferred. This is not because it is the best description of the labour market in all circumstances (wage bargaining between employers and workers is observed), just that it is a better description most of the time. For example, chapter 5 documents the existence of a substantial number of firms (in labour markets without minimum wages or trade unions) that pay all their workers in a particular job the same wage. It is hard to see how this could be the outcome of individualised ex post wage bargaining between employers and workers given the heterogeneity of workers within the firms. Even in labour markets that one thinks of as being highly individualistic such as Wall Street, employers seem reluctant to engage in more than limited negotiation: Lewis (1989, p149) describes how Salomon Brothers lost their most profitable bond-trader because of their refusal to break a company policy capping the salary they would pay. Models of wage-posting seem to provide a better description of reality.

But, economists often also judge theories not by the realism of their assumptions but by the quality of their predictions. Comparing wage-posting and wage bargaining models on this basis is difficult because so many of the predictions are the same and it may not matter greatly which assumption about wage determination is used in many circumstances. There is a good

---

10 However, there are some substantive differences. Ex post wage bargaining implies that all efficient matches will be consummated whereas ex ante wage-posting may result in some efficient matches failing to be consummated (for example, an unemployed worker with a particularly high reservation wage may not want the job at the offered wage even though there is a higher wage at which both employer and worker would gain from
reason for this: even though monopsony models appear to give all the bargaining power to the employer, both monopsony and matching models predict that the rents of the employment relationship get shared between workers and employers. In monopsony models, workers get some share of the surplus as long as employers are not perfectly discriminating monopsonists (and chapter 5 will argue that there are good reasons why they cannot be). Assuming that firms set wages and are, at least in a formal sense, monopsonists, should not be taken to imply that their share of any rents is necessarily large.

Another advantage of the monopsony over the matching approach is that it is much easier to forge links with other parts of labour economics. Although the underlying model of the labour market with frictions may be relatively complicated with a lot of dynamics and value functions, one can often represent and understand the decision problem of the individual employer in the monopsony model in terms of the textbook static model of monopsony. In contrast, the matching models do not have a simple static textbook counterpart model and the use of these models has led to unfortunate parallel literatures in which the same labour market phenomenon is ‘explained’ by both a matching model and a conventional static model without the fundamental similarity between them being recognized. From those who specialize in the analysis of matching models, one often hears the claim that ‘dynamic models are different’ to justify this state of affairs: while there is some truth in this statement it is much less true than they commonly think. And empirical labour economists often feel that there is little benefit in terms of understanding and a considerable cost in terms of analytical complexity from using a dynamic

---

11 Some might object to the use of the word monopsony in a situation in which workers get some or even most of the rents. But, consumers are strictly better-off with electricity than without although most people would be content with the description of the utility as a monopolist. The use of the word >monopsony< is simply meant to refer to the fact that employers set wages.
model and fall back on the familiar textbook model of perfect competition.

Hence, although one should think in terms of monopsony and matching models as being fundamentally similar models of the labour market, the monopsony model is a better description of the way labour markets work and makes it much easier to forge links with the rest of labour economics.

1.4 Antecedents

As has already been pointed out, a number of distinguished economists viewed labour markets as operating in the way described in this book and that bits and pieces of modern labour economics are, implicitly or explicitly, analyses of monopsonistic or oligopsonistic labour markets. But there are two particular traditions that I want to single out as being important influences on this work.

The first is the labour economics of the so-called neo-realist or neoclassical revisionist labour economists (Kaufman, 1988) who thrived in the United States in the late 1940s and the 1950s before being supplanted by economists who drew their inspiration from Hicks’ “Theory of Wages” and from the Chicago school of thought. These economists like John Dunlop, Clark Kerr, Richard Lester and Lloyd Reynolds had been brought up on neo-classical economics but felt that the competitive model gave a seriously inaccurate picture of how labour markets operated.

There were two main reasons why they arrived at this conclusion. First, studies of labour mobility seemed to show that workers were extremely reluctant to change jobs and hence that the mechanism which was imagined to enforce the competitive law of one wage was, in reality, much weaker than most labour economists imagined. One consequence of this was that the market did not dictate the wage an employer had to pay or face ruin: employers had, in fact,
considerable discretion in the wage that they chose to pay. Further evidence of this was the considerable dispersion in wages found in labour markets defined very tightly in terms of occupation and area (Lester, 1946, 1948; Slichter, 1950; Reynolds, 1946a,b, 1951; Dunlop, 1957 amongst others). They were well aware of the possibility that such wage dispersion might be driven by differences in the non-wage aspects of jobs or differences in worker quality or be only short-term (see, for example, the discussion in Lester, 1952, p487-8) but they arrived at the conclusion (often more by the exercise of judgment than firm evidence) that the wage dispersion was real and permanent. The practical experience of several of these economists in the work of the War Labor Board which set out to find the market wage for particular classes of labour and found only wage dispersion was particularly important in convincing them that the competitive model suffered from serious deficiencies.

These economists were actively discussing the supply curve of labour to the firm, the issue that is at the heart of this book. Reynolds (1946a) wrote a paper entitled AThe Supply of Labor to the Firm@ in which he wrote that Athe view that labor-market imperfections result in a forward-rising supply curve of labor to the firm appears to have been first elaborated by Mrs. Robinson. This conclusion has made its way rapidly into the textbooks and seems well on the way to being generally accepted as a substitute for the horizontal supply curve of earlier daysA (p390). It is hard to imagine a paper with this title in the journals of today let alone a statement along these lines. And Bronfenbrenner (1956) wrote that Athe typical employer in an unorganized labor market is by no means a pure competitor facing market wages which he cannot alter. The mobility of the labor force, even between firms located close together, is low by reason of the inability of workers to wait for employment or risk unemployment, plus the inadequacy of the information usually available to them regarding alternative employment opportunities. This low mobility permits each employer to set his own rates and form his own
labour market within limits which at some times may be quite wide. In the technical jargon of economic theory, the typical employer in an unorganized labor market has some degree of monopsony power and can set his own wage policy (p578), a statement of the central themes of this book which it would be hard to better.

So these economists were writing about the issues on which I will write and thinking about explanations along the same sort of lines. Yet, I cannot help feeling that these labour economists would not necessarily welcome my embrace. My bald assumption that employers set wages to maximise profits is the kind of crass generalisation from which someone like Lester instinctively recoiled. He came to emphasize how the lack of cutthroat competition in the labour market gave leeway for employers to pursue many ends and this was, for example, one explanation of wage dispersion observed (see, for example, Lester, 1952). Perhaps this was because he saw any model based on a single objective (like profit maximisation) predicting a determinate outcome, a prediction that was then obviously falsified by observation of the world. But, the general equilibrium models that are used (see, for example, the model of section 2.4) have as an equilibrium a range of wages even when the objectives pursued by all firms are identical: in a sense they are models of determinate indeterminacy.

While Reynolds wrote about the supply curve of labour to the firm his final conclusion was that “in actuality, an employer can usually expand and contract employment at will without altering his terms of employment” (Reynolds, 1951, p227) so that the competitive labour supply curve gave the right answer though for the wrong reasons. He arrived at this conclusion primarily because of the observation that it did not seem to cost much in terms of time or money.

---

12 If one looks at the representative quotes about monopsony in the textbooks authored by these economists it would be hard to see any more favourable inclination to monopsony than is found in the others.

13 Though Lester’s position does receive some support if one tweaks our basic model to introduce mobility costs and preferences over non-wage job attributes when multiple equilibria tend to be rife.
to recruit extra workers i.e. vacancy durations were (and are) extremely low. This is a serious objection to the relevance of the monopsony model and one which I will discuss at length in chapter 10. But my conclusion will be different: I will argue that what we know about vacancies is perfectly consistent with the existence of non-negligible monopsony power.

The other important inspiration for this book is a single paper: Burdett and Mortensen (1998). I saw this paper presented at the LSE in 1990 and it was a revelation to me. Here was a simple elegant analytical framework that could explain the existence of equilibrium wage dispersion (and other stylized facts about the labour market). If I had not been quite so ignorant I would have realized that proving the possibility of equilibrium price or wage dispersion was not as new or as difficult as I had imagined (one might cite Butters, 1977; Salop and Stiglitz, 1977; Reinganum, 1979; Burdett and Judd, 1980; Albrecht and Axell, 1984; Lang, 1991; Montgomery, 1991 among others which did more or less the same thing). But the advantage of the Burdett and Mortensen model to me was that whereas many of the other models of price or wage dispersion were too stylized to be able to take to labour market data, their model was expressed in terms of quit and recruitment rates, and job offer arrival rates that had obvious empirical counterparts. So it is their model that forms the basis of much of what follows, though I imagine that one could have built much of it on some of the other papers.

1.5. **Summary of chapters and main results**

This book is based on two assumptions:

S there are important frictions in the labour market

S employers set wages

The consequence of the first assumption is the employers have market power in the labour

---

14 It may have been published in 1998 but was originally written at least 10 years earlier.
market and the consequence of the second is that they exercise it. The labour supply curve facing an employer is not infinitely elastic so that employers have some monopsony power.

The style of this book is to systematically apply these two assumptions to most areas of labour economics. Each chapter presents both the relevant theory and empirical evidence based on US and UK data. Every attempt has been made to make the main body of each chapter as accessible as possible with the proofs of the propositions and more technical material confined to an Appendix at the end of each chapter. And, because the same data sets are used throughout, there is also, at the end of the book, a Data Sets Appendix, providing details of how the data were constructed.

The book is divided into four parts. In the first part, chapters 2 through 4, some basic models and results are laid out.

Chapter 2, ‘Simple Models of Monopsony and Oligopsony’ starts by presenting some partial equilibrium models of static and dynamic monopsony. While these partial equilibrium models are adequate for analysing many questions, there are others for which it is necessary to model interactions between employers i.e. to model the labour market as oligopsonistic. The chapter then presents a model of oligopsony based on the wage-posting model proposed by Burdett and Mortensen (1998).

The chapter derives the well-known result that the extent of employer monopsony power is related to the wage elasticity in the labour supply curve facing an individual employer: the less elastic the supply curve, the more market power the employer possesses. It also argues that the greater the ability of workers to move from employer to employer, the more wages will be driven up towards their marginal product. It suggests that the proportion of workers recruited directly from other jobs is a good simple measure of the competitiveness of labour markets. For both US and UK data sets this proportion is shown to be in the region
of 45-50%, a level that is argued to suggest employers have substantial market power.

Chapter 3, ‘Efficiency in Oligopsonistic Labour Markets’, considers the welfare implications of oligopsonistic labour markets in variations on the model of Burdett and Mortensen (1998). Most of the book is about the positive implications of assuming that employers have market power over their workers. But while ‘monopsony’ as used in this book should be interpreted as a technical term to describe the situation where the labour supply curve to the firm is not infinitely elastic, the term often has more emotive connotations and is sometimes taken to imply that, in some sense, wages are ‘too low’. This is certainly true for the textbook analysis of a single monopsonist where, if the employer has market power, one can always find a binding minimum wage that raises employment and welfare. However, as chapter 3 shows, this simple conclusion breaks down once one moves beyond the case of the single monopsonist. The main conclusion of the chapter is that the free market equilibrium is generally not efficient but that interventions like the minimum wage may improve or worsen efficiency, depending on the particular model being considered. Hence the chapter concludes that theory alone can be of little use in evaluating policy.

The final section of chapter 3 presents a simple model of a ‘ghetto’, emphasizing how, in labour markets with frictions it is relatively simple to generate multiple equilibria and agglomeration effects. For example, residents of a neighbourhood may not invest in human capital if they think there are no jobs in which to use them while employers may not locate in an area in which the residents have low levels of human capital. In a market with frictions, there is no mechanism to ensure that an act of investment in human capital by an individual will bring forward the investment of physical capital to employ it.

Chapter 4, ‘The Elasticity of the Labour Supply Curve to an Individual Firm’ presents
evidence on the wage elasticity of the labour supply curve to the individual employer. This is the natural place to start for making the case that monopsony is empirically relevant as the assumption that the labour supply curve to individual employers is not perfectly elastic is the fundamental idea in monopsony. There are astonishingly few papers in the labour economics literature on the supply of labour to individual employers in contrast to the volumes written about labour demand and individual labour supply to the market as a whole.

In estimating the supply curve to an individual employer, the obvious place to start is to regress log wages on the log of employment (plus other relevant controls). One finds, consistent with monopsony, a very robust positive correlation between wages and employment. This employer size-wage effect is well-known in labour economics though it is rarely interpreted as evidence of an upward-sloping labour supply curve to an individual employer. The chapter reviews the more common explanations for the employer size-wage effect, concluding that none of them can explain it all and that part of the employer size-wage effect does seem to be the result of an upward-sloping supply curve of labour to the individual employer. However, once one has controlled for other relevant factors, the elasticity of wages with respect to employment is often low, in the region of 0.04 implying that the elasticity in the labour supply curve to the employer is high – about 25. But, these OLS estimates are likely to be biased downwards because shifts in the supply of labour to the employer will tend to induce a negative correlation between wages and employment. Reverse regressions in which employment is regressed on wages suggest a much lower wage elasticity of the labour supply curve – often in the range of 1.5-3.5. Finding a suitable instrumental variable is the obvious way to try to sharpen up these estimates but that is not an easy task as the instrument needs to be firm-specific. The few studies that do take this approach suggest that labour supply to individual firms is relatively inelastic.
The second half of chapter 4 takes a different approach to estimating the labour supply elasticity, one based more explicitly on a dynamic model of monopsony. As, in steady-state, employment, \( N \), is equal to the recruitment rate, \( R \), divided by the separation rate, \( s \), \( (N=R/s) \), the wage elasticity of employment can be written as the wage elasticity of recruitment minus the wage elasticity of separations. There is a relatively large existing literature that estimates the sensitivity of separations to the wage but estimating the elasticity of recruits is more difficult. However, it is shown how in models of dynamic oligopsony there will be a tight relationship between the separation and recruitment elasticities. In the simplest model, they must be equal to each other and, in more complicated models, a weighted average must be equal. Using this approach the wage elasticity of the labour supply curve to an individual employer is estimated to be in the region of 0.75-1.5 i.e. relatively low.

The second part of the book, chapters 5 through 8, is about how monopsony can help us towards a better understanding of the observed distribution of wages.

Chapter 5, ‘The Wage Policies of Employers’, discusses the incentives for employers to pay different wages to identical workers, i.e. to become a discriminating monopsonist, and the difficulties with doing so. For example, employers would like to be able to pay low wages to workers with low reservation wages but it may be very difficult to observe reservation wages. Employers are more likely to base wage discrimination on non-manipulable characteristics of the workers like job tenure and age. The chapter shows how there are incentives for employers to use seniority wage schedules in line with what is observed. However, it is argued that there are good theoretical reasons and empirical evidence to suggest that the ability to wage discriminate may be severely limited in practice.

Chapter 6, ‘Earnings and the Life-Cycle’ examines the way in which earnings evolve over a working life. The human capital approach to this question emphasizes the way in
which both general and specific human capital accumulate over a lifetime and empirical
correlations of earnings with experience (or age) and job tenure are normally interpreted in
the light of the human capital model. Section 6.1 starts by presenting evidence that there is
something wrong with this way of interpreting earnings functions. For example, the earnings
losses of displaced workers are increasing in the level of experience, something that should
not happen if the returns to experience represent the returns to general human capital. Section
6.2 then shows that a substantial part of the observed cross-sectional returns to job tenure is
the result of the bias caused by the fact that those in high-wage jobs are less likely to leave
them.

Section 6.3 then introduces a job-shopping model as a way to explain correlations
between wages, age and job tenure even if the wage offer distribution does not depend on age
and job tenure. For example, there may be a correlation of wages with age because older
workers are more likely to have found the better-paying jobs (Burdett, 1978). One can then
explain why more experienced workers suffer larger wage losses after displacement as job
loss causes a reduction in ‘search capital’. And there may be a correlation of wages with job
tenure as those who have been lucky enough to find a high-paying job are less likely to leave
it. However, as section 6.3 makes clear, the correlations predicted by the search model are
more complicated than this simple discussion suggests.

Section 6.4 then proposes a new framework for decomposing the life-cycle profile
of earnings into three components: the growth in earnings on the job, the costs of job loss and
the return to job mobility. It is shown how the returns to job tenure as conventionally
measured are a weighted average of the change in the costs of job loss and the returns to job
mobility but that this mixes up two very different processes as job mobility is mostly
voluntary on the part of workers leading to wage gains while job loss is involuntary leading
to wages losses.

The final two sections then present two applications of this approach: to estimating the returns to job mobility and the decline in average earnings among older men. It is shown how the decline in earnings among older men is primarily the result of substantial rates and costs of job loss.

Chapter 7, ‘Discrimination in Labour Markets’ discusses how monopsony can help us understand the gender pay gap. It is argued that the weaker attachment of women to the labour market can go some way towards explaining the gender pay gap even if there is no gender productivity gap. The reason is that women will find it harder to work their way into the better-paying jobs. Furthermore, evidence is presented that women are less motivated than men by money in choosing jobs so that the female labour market is likely to be more monopsonistic than the male. Section 7.4 presents evidence for this from responses to questions on the motivation for changing jobs and section 7.5 presents evidence that the returns to job mobility are lower for women than for men. Human capital explanations of the gender pay gap also emphasize the weaker attachment of women to the labour market as a source of the gender pay gap but argue that this results in lower productivity. Two pieces of evidence inconsistent with this view are presented: in section 7.7, it is shown how the returns to job tenure are, if anything, larger for women than for men while section 7.8 analyses the impact of the 1970 UK Equal Pay Act that resulted in a large increase in female relative wages but had no impact on relative employment contrary to the predictions of the human capital model.

Chapter 8, ‘Employers and Wages’, considers the well-known empirical ‘puzzle’ that employer characteristics are correlated with wages. In a competitive market these correlations should not exist (abstracting from compensating wage differentials that do not
seem to be empirically that important) as the wage should be determined solely by the characteristics of workers. However, as shown in section 8.1, we would expect wages to vary with employer characteristics like size, productivity and profitability if employers have some market power. The ‘puzzle’ is simply what we would expect.

Sections 8.2 and 8.3 discusses the implications of monopsony for the estimation of compensating wage differentials. It is argued that the conventional approach to estimating the value of non-pecuniary aspects of jobs that is based on estimating earnings functions is flawed if employers have market power as there is no reason to believe that utility is equalized across jobs in the labour market. In particular, there is good reason to think that utility will be lower in jobs with worse work conditions. An alternative approach to estimating the value of non-pecuniary benefits based on estimating separation functions is proposed and an application to estimating the disamenity associated with night work is presented. Section 8.4 discusses the likely effect of mandated benefits, intervention to regulate the non-wage conditions of work e.g., health and safety legislation, maximum hours legislation etc. In a competitive labour market it is often argued that such legislation is likely to be bad as it imposes an inefficient wage-benefit combination and may actually harm rather than help workers. However, it is shown that this is not necessarily the case if employers have some market power: regulation of non-wage aspects of jobs will make workers better-off as long as the non-wage attribute is a ‘normal’ good and the regulation is not too onerous.

Finally, section 8.5 applies the framework established earlier in the chapter to the analysis of hours of work. The determination of hours of work as considered in the labour supply literature is normally treated as a completely different subject from the analysis of other non-wage job attributes. But there is no good reason for this: given the level of earnings, higher hours increase output and reduce worker utility just like any other non-wage
attribute. It is argued that, if employers have monopsony power, then workers are likely to be over-worked in the sense of being forced to work more hours than they would like given their wage.

The third part of the book, chapters 9 through 11, is then concerned with the ‘quantity’ side of the labour market, the supply of and demand for labour and the determinants of investment in human capital.

Chapter 9, ‘Unemployment Activity and Labour Supply’ considers the determinants of the level and structure of unemployment and inactivity from the perspective of the worker. The employment rate of an individual worker is determined by the rate at which they get jobs when not in employment and lose them when in employment. The main way in which an individual can influence the rate at which they get jobs is by their choice of job search activity. Section 9.1 endogenizes the choice of search intensity both on- and off-the-job. The relative effectiveness of these two types of job search is important and a new test is proposed based on the fact that the reservation wage should depend positively (negatively) on the productivity of workers as off-the-job search is more (less) effective than on-the-job search. This empirical evidence strongly suggests that off-the-job search is more effective. Section 9.2 then discusses the distinction between unemployment and inactivity as defined in labour market statistics. Competitive models of the labour market do not have a meaningful distinction between these two labour market states but because the unemployed are defined as those with job search intensity above a critical level, the framework of this chapter makes the distinction easy to understand. An application to the discouraged worker effect suggests that, when aggregate labour market conditions worsen, job search intensity falls resulting in a rise in measured inactivity rates.

Section 9.3 considers the job search intensity of the employed. Monopsony has a
strong prediction, that job search activity should be declining in the wage as there are then fewer opportunities to find a better job. The empirical evidence reported is strongly in support of this prediction. Section 9.4 then considers the determinants of the rate at which workers will quit jobs for non-employment. Consistent with the empirical evidence, the model predicts that quit rates will be declining in the wage.

Sections 9.6 and 9.7 are concerned with conceptual issues about the nature of unemployment in labour markets where employers have market power. In the simplest models of monopsony, unemployment appears ‘voluntary’ in the sense that all employers would like to hire more workers at the going wage. This seems hard to reconcile with the observation that jobs often seem to be hard to find and the feeling that many economists have that unemployment is ‘involuntary’. However, as sections 9.6 and 9.7 show it is a simple matter to reconcile models of monopsony with models of involuntary unemployment (represented by efficiency wage models).

Chapter 10, ‘Vacancies and Labour Demand’, considers the determinants of the level of employment from the perspective of employers. Sections 10.1 and 10.2 are concerned with the interpretation of vacancy statistics. It is argued that, to have a meaningful model of vacancies, one has to have a model in which the creation of jobs requires some ex ante investment and in which the supply of labour to the firm is stochastic. With these features, a model of the labour market in which employers have considerable market power is quite consistent with the observation that vacancy rates are low, vacancies are typically of short duration and have relatively small numbers of applicants. Empirical evidence supports the conclusion that those firms that pay higher wages have fewer difficulties in filling vacancies.

Sections 10.3 and 10.4 are concerned with the technology by which workers and employers are matched. A crucial issue turns out to be whether large employers have an
intrinsic advantage over small firms in recruiting workers, because this is important in
determining the wage elasticity in the supply of labour to the firm. However, it is shown that
large employers are not more likely than small firms to use recruitment methods in which
they might be thought to have an advantage like social contacts.

Section 10.5 returns to an issue previously discussed in the generalised monopsony
model of section 2.3. There the dividing line between perfect competition and monopsony
was shown to be whether there are increasing marginal costs of recruiting and retaining
workers. This is a difficult issue to assess empirically because of the comparative rarity of
data on recruitment costs. However, section 10.5 shows, using UK data, that there do seem
to be increasing marginal costs of recruitment.

Finally section 10.6 contains a brief discussion of the determination of lay-offs,
arguing that there are good reasons to think that they will occur while there is still some
surplus in the relationship remaining for workers.

Chapter 11, ‘Human Capital and Training’, considers the incentives for the
acquisition of human capital in monopsonistic labour markets. Section 11.1 considers the
incentives for workers to engage in the acquisition of education before they enter the labour
market. Because part of the returns to any such education are likely to accrue to future
employers of the worker, there is a prima facie case for believing there will be under-
investment in human capital. However, there is some reason to believe that the labour market
for more educated workers may be less monopsonistic in which case it may be that this
conclusion is misleading. Section 11.2 then considers the provision of employer-provided
general training. A key prediction of the monopsony model which contrasts very strongly
with that of the competitive model is that employers will be prepared to pay for some
investments in general training because they can expect to get some returns from it.
However, because future potential employers of a worker might also expect to get a share of the returns from any investment in human capital, one would expect to see under-investment. Section 11.3 then considers firm-specific training. A striking conclusion is that workers may capture a higher share of the returns to firm-specific investments than of general investments if employers have market power. Finally, section 11.4 concludes with a discussion of the empirical evidence on training.

The final part of the book, chapters 12 and 13, considers the impact of institutions that interfere with the ability of employers to see wages and draws some conclusions.

Chapter 12, ‘Minimum Wages and Trade Unions’ is concerned with the impact of these wage-setting institutions on wages and employment. Although these institutions are often seen as essentially similar (they both raise wages above the market-clearing level), their effects in a monopsonistic labour market are likely to be rather different. For example, minimum wages have a direct impact on the lowest wages in a given labour market so are likely to ‘push’ the wage distribution from below while trade unions are likely to set the highest wages in a given market so will ‘pull’ the wage distribution from above. Section 12.1 discusses the impact of the minimum wage on the wage distribution. Empirical evidence is presented that spill-over effects from the minimum wage onto the US wage distribution are substantial. Section 12.2 then argues that much of the evolution of wage inequality in the bottom half of the U.S. wage distribution from 1980-2000 can be explained by variation in the minimum wage. Section 12.3 then discusses the controversial issue of the impact of the minimum wage on employment. While a minimum wage does not necessarily cost jobs in an oligopsonistic labour market, it is shown that the simple result from the model of a single monopsonist that a suitably chosen minimum wage must raise employment does not carry over to a labour market in which one models interactions between firms and heterogeneity
among them. An open-minded empirical approach is appropriate for investigating the impact of minimum wages on employment.

Section 12.4 discusses how models of trade unions need to be modified to recognize the fact that employers have some market power. It also discusses the argument that ‘corporatist’ systems of wage bargaining can do something to alleviate the problems caused by a ‘free market’ system of wage determination. Section 12.5 discusses the impact of trade unions on wages. It focuses on the impact of unions on non-union wages, arguing that in a labour market where employers have some power over wages, the impact of unions on non-union wages is likely to depend on whether on- or off-the job search is more effective. The evidence presented in chapter 9 suggests that off-the-job search is more effective in which case unions would be expected to raise non-union wages. Empirical evidence for this is presented and it is argued that the correlations cannot be explained by the ‘threat’ effect.

Chapter 13, ‘Monopsony and the Big Picture’ offers some conclusions. Section 13.1 reviews the sources of monopsony power and the evidence that employers have it. Section 13.2 argues that recognizing the existence of monopsony power in the labour market does not mean supplanting all existing competitive analysis: in many cases, it simply adds to it. One might wonder about how important monopsony is in understanding the ‘big’ issues of the day. Section 13.3 addresses this argument by arguing that a view that the labour market is monopsonistic is necessary for an adequate understanding of changes in the bottom half of the US labour market since 1980. Section 13.4 then discusses what monopsony has to say about the design of labour market policy. The main substantive conclusion is that labour economists should be more open-minded about the likely impact of labour market interventions: empirical evidence is more powerful than theory. Too often (for example, in discussions of European unemployment), labour economists simply assume (often
unthinkingly) that the alternative to a regulated labour market is a labour market that is well-approximated by the perfectly competitive model.

In the book as a whole, virtually all of the main topics of labour economics are covered although not necessarily in a familiar order. So, Table 1.2 presents a simple key for where some topics may be found in this book.
